Introduction

Chapter 1

Introduction

In this thesis we will be looking at the language mechanism Package Templates and the language TypeScript and how this language mechanism fits into the language.

Package Templates

1.1 What is PT?

1.2 Purpose of Implementing PT in TS

1.3 Structure of Thesis

In part one of this thesis we will focus on getting to know the language mechanism Package Templates, and get a proper understanding of the programming language TypeScript and its ecosystem in [chapter 2 on page 5](#).

With a proper understanding of these topics we will move on to the second part of the thesis. This part will focus on the implementation of the project. The part starts off by planning out and designing the language PTS in [chapter 3 on page 19](#). PTS, short for Package Template Script, will be a superset of TypeScript with a basic implementation of the language mechanism PT. [Chapter 4 on page 25](#) will then focus on making a plan for the implementation of our programming language. Here we will perform a requirement analysis of the project and seek out an approach for the implementation. With a plan for approach and execution we will discuss the resulting implementation of the compiler in [chapter 5 on page 29](#).

In the final part of this thesis we will discuss the resulting implementation. This discussion starts off in [chapter 6 on page 41](#) where we will be examining the implementation, looking at whether it fulfills the requirements of PT. After this we will be comparing our implementation of Package Templates to another implementation of PT in Java in [chapter 7 on page 51](#), looking at the advantages and disadvantages of having PT in a structurally typed language.

Chapter 2

Background

2.1 Package Templates

Krogdahl proposed Generic Packages in 2001, which is a language mechanism aimed at "large scale code reuse in object-oriented languages" [8]. The idea behind this mechanism is to make modules of classes, called *packages*, that could later be imported and instantiated. This would make "textual copies" of the package body, and would also allow for further expanding the classes of the packages. Modularizing through Generic Packages made the programming more flexible as you would easily be able to write modules with a certain functionality and be able to later import it several times when there is a need for the functionality.

Generic Packages was later extended, and the mechanism is now called Package Templates (while the textual program modules themselves are simply called templates). The system is not fully implemented and there exists a number of proposals for extending it.

2.1.1 Basics of Package Templates

In this section we will look at the syntax of Package Templates (further referred to as *PT*) in a Java-like language as proposed in [9].

Defining packages and package templates

Packages are defined by a set of classes similar to a normal Java package. Package templates (later just templates for short), are defined in a similar manner except for using the keyword *template*. Listing 1 on the next page shows an example of defining packages and templates. The contents of a package can be used as you would with a normal Java package.

Instantiating templates

Instantiating is what really makes PT useful. When defining packages and templates, PT allows for including already defined templates through instantiating. Instantiation is done inside the body of a package (or a template) with the use of an `inst`-clause. Instantiating a template will make

```
package P {  
    interface I { ... }  
    class A extends I { ... }  
}  
  
template T {  
    class B { ... }  
}  

```

Listing 1: Defining a package P and a template T

"textual copies" of the classes, interfaces and enums from the instantiated template and insert them replacing the instantiation statement at compile time. Note that the template itself still exists and that it can be instantiated again in the same program. Listing 2 on the facing page shows an example of instantiating a template inside a package. The resulting package P will then have the classes A and B from template T and its own class C.

Renaming

During instantiation it is possible to rename classes (as well as interfaces and enums) and *class attributes*. Here and henceforth we will be using the term class attributes to describe the union of both the fields and the methods of a class. Renaming is a part of the instantiation of templates, and will only affect the copy made for this instantiation, and it is done for the copy before it replaces the `inst`-statement. Renaming is denoted by an optional `with`-clause at the end of the `inst`-statement. In the `with`-clause one can rename classes using the following fat arrow syntax, `A => B`, where class A is renamed to B, and rename class attributes with a similar arrow syntax, `i -> j`, where the attribute `i` is renamed to `j`. For method renaming you have to give the signature of the method so that it is possible to distinguish between overloaded versions, i.e. `m1(int) -> m2(int)`. On a more technical level the compiler will find the class or attribute declaration that is going to be renamed, and then find all name occurrences bound to this declaration and rename these.

Field renaming comes after the class renaming enclosed by a set of parentheses. Renaming classes will also affect the signatures of any methods using this class. Listing 3 on page 8 shows an often used example of renaming, where a graph template is renamed to better fit a domain, in this case a road map. When renaming the class `Node` the signature of the methods in `Edge` using this `Node` was also changed to reflect this, i.e. the method `Node getNodeFrom()` would become `City getNodeFrom()` with the class rename, and `City getStartingCity()` with the method renaming.

Renaming makes it possible to instantiate templates with conflicting names of classes, or even instantiate the same templates multiple times. Listing 4 on page 9 shows an example of this where we instantiate the same template T twice without any issues.

```
// Before compile time instantiation of T
template T {
    class A { ... }
    class B { ... }
}

package P {
    inst T;
    class C {
        A a;
        B b() {
            ...
        }
    }
}

// After compile time instantiation of T
package P {
    class A { ... }
    class B { ... }
    class C { ... }
}
```

Listing 2: Instantiating template T in package P. Note that class C can reference class A and B as if they were defined in the same package, which they essentially are after the instantiation.

```
template Graph {
  class Node {
    ...
  }

  class Edge {
    Node getNodeFrom() { ... }
    Node getNodeTo() { ... }
  }

  class Graph {
    ...
  }
}

package RoadMap {
  ...
  inst Graph with
    Node => City,
    Edge => Road
    (getNodeFrom() -> getStartingCity(),
     getNodeTo() -> getDestinationCity()),
    Graph => RoadSystem;
  ...
}
```

Listing 3: Example of renaming classes during instantiation. This could be used to make the classes fit the domain of the project better.

```
template T {
    class A {
        void m() { ... }
    }
}

package P {
    inst T;
    inst T with A => B;
}

// package P after compile time instantiation and renaming
package P {
    class A {
        void m() { ... }
    }

    class B {
        void m() { ... }
    }
}
```

Listing 4: Example of instantiating the same template twice solved by renaming.

```
template T {
    class A {
        void someMethod() { ... }
    }
}

package P {
    inst T;
    addto A {
        int i;
        void someOtherMethod() { ... }
    }
}
```

Listing 5: Adding new attributes to the instantiated class A in package P

Additions to a template

When instantiating a template you can also add attributes to the classes of the template, as well as extending the class' implemented interfaces and this will only apply to the current copy. These additions are written inside an `addto`-clause. Extending the class with additional attributes is done in the body of the clause, like you would in a normal Java class. If an addition has the same signature as an already existing method from the instantiated template class, then the addition will override the existing method, similarly to traditional inheritance. Listing 5 shows an example of adding attributes to an instantiated class. The resulting class A in package P would have the field `i` and the methods `someMethod` and `someOtherMethod`.

It is also possible to extend the list of implemented interfaces of a class by suffixing the `addto`-clause with a `implements`-clause containing the list of implementing interfaces. Having the possibility to add implementing interfaces to classes makes working with PT easier and enables the programmer to re-use template classes to a much larger degree. This feature's use is easier explained through an example.

Say we have implemented some class that will deal with logging. This class can log the state of a class given that the class implements some interface `Loggable`. If we want to be able to log the state of our Graph implementation, from [3 on page 8](#), then the Graph class would need to implement the `Loggable` interface. We can't do this at the declaration of the Graph template, as we do not have access to the interface at the time of declaration. By using `addto` however we are able to add the `Loggable` interface and the `log` method to the Graph class. You can also achieve the same functionality through class merging, which we will look at in [section 2.1.1 on page 12](#).

```
template Logger {
    interface Loggable {
        String log();
    }

    class Logger {
        void log(Loggable loggable) {
            ...
        }
    }
}

package P {
    inst Graph;
    inst Logger;
    addto Graph implements Loggable {
        String log() {
            ...
        }
    }
}
```

Listing 6: Adding the Loggable interface to the Graph class from listing [3 on page 8](#), making it compatible with our logger implementation.

```
template T1 {  
    class A {  
        ...  
    }  
}  
  
template T2 {  
    class B {  
        ...  
    }  
}  
  
package P {  
    inst T1 with A => C;  
    inst T2 with B => C;  
}
```

Listing 7: Instantiation with class merging through renaming

Merging classes

If two or more classes in the same or in different instantiations in one package share the same name they will be merged into one class. Through this mechanism PT achieves a form of multiple inheritance. This form of inheritance is different from what you would normally find in Java, it acts more like *mixins* (a language feature for injecting code into a class, first introduced in the programming language Jigsaw [3]). The merging of the classes will not lead to a classic superclass-subclass relation, as the merged class is simply a concatenation of textual copies of the merging classes. We call this kind of inheritance *static multiple inheritance*.

If two classes don't share the same name, it is still possible to force a merge through renaming them to the same name. In listing 7 we see an example of renaming class A from template T1 to C and class B from template T2 to C. Renaming these two classes to the same name will force these classes to be merged in package P. The result of this merge is a new class C with the attributes of both classes. The two classes A and B, from templates T1 and T2 respectively, no longer exists in package P, but have formed the new class C, which is a union of both. Any pointers typed with the old A or B will now be typed as the new merged class C.

2.1.2 Advanced Topics of PT

With a firm understandings of the basics of PT we will now have to dig a bit deeper into some terminology and restrictions of the language mechanism.

Open and Closed Templates

A *closed template* is a template that does not contain any instantiation statements nor any additions to classes, it comprises only classes, interfaces and enums. The body of a closed template in Java is simply a Java program. Closed templates are self-contained units that can be separately type-checked [2]. An *open template* on the other hand is a template which has one or more instantiations or `addto`-statements in its body.

Open templates will be closed at compile-time. The task of closing a template is that of performing the contained instantiations and additions to classes. Open templates can instantiate open templates, as long as these instantiations are not cyclic. What this means is that a template A can instantiate a template B if template B does not contain any instantiations of template A. A template B contains an instantiation of template A if it has an instantiation of template A in its body, or contains a nested instantiation of template A.

Packages can also be open and closed and work in the same manner as with templates, except that they can not be instantiated.

`tsuper`

Avoiding Indirect Multiple Inheritance

While PT enables the programmer to merge classes together and giving us some form of static multiple inheritance, it is not intended to actually enable multiple inheritance. However, with class merging, it is not uncommon that a class might end up with two or more different superclasses. To avoid this PT has some restrictions to stop this from happening.

The first restriction is that external classes, classes defined outside the template, can not be used as a superclass. This might seem harsh at first, but it is still possible to implement interfaces outside the template, and this should circumvent most of the drawbacks these restrictions places upon us.

The second restriction is that if two or more classes are merged in an instantiation, then their superclasses must also be merged in the same instantiation. This is to avoid the situation where merging two classes results in two or more different superclasses [9].

2.2 TypeScript

Before we look at what TypeScript is we first need to understand JavaScript and the JavaScript ecosystem.

2.2.1 JavaScript

Back in the mid 90s web pages could only be static, however there was a desire to remove this limitation and make the web a more interactive

platform, as it became increasingly more accessible to non-technical users. In order to remove this limitation, Netscape, with its Netscape Navigator browser, partnered up with Sun in order to bring the Java platform to the browser, and hired Brendan Eich to create a scripting language for the web. Eich was tasked to create a Scheme like language with syntax similar to Java, and the language was intended to be a companion language to Java. The language when it first released was called LiveScript, however it was later renamed to JavaScript. This has been characterized as a marketing ploy by Netscape in order to give the impression that it was a Java spin-off.

Microsoft, with its Internet Explorer, adopted the language and named it JScript. During this time Microsoft and Netscape would both ship new features to the language in order to increase the popularity for their respective browsers. Because of this war between browsers the language was later handed over to ECMA International as a starting point for a standard specification for the language. This ensured that users would get the same experience across different browsers, making the web more accessible [24].

A web page generally consists of three layers of technologies. The first layer is HTML, which is the markup language that is used to structure the web page. Second is CSS which gives our structured documents styling such as background colors and positioning. The third and final layer is JavaScript which enables web pages to have dynamic content. Whenever you visit a website that isn't just static information, but instead might have timely content updates, interactive maps, etc., then JavaScript is most likely involved [14].

JavaScript, or more precisely ECMAScript, is the programming language of the web. It is a language that conforms to the ECMAScript specification. ECMAScript is simply a JavaScript standard, created by Ecma International, made to ensure interoperability across different browsers. There is no official runtime or compiler for JavaScript as it is up to each browser to implement the languages runtime. When we create a JavaScript program/script for a web page we don't compile it and transfer a binary or bytecode file for the web page to execute, instead the browser takes the raw source code and interprets it¹.

JavaScript is a multi-paradigm language with dynamic typing...

ECMAScript Versions

ECMAScript versions are generally released on a yearly basis. This release is in the form of a detailed document describing the language, ECMAScript, at the time of release. New versions will most likely include some additions to the language, but never any breaking changes². This is because the developer will not be able to control the environment on which the code will be executed since you can not be sure which ECMAScript

¹On a more technical level, JavaScript is generally just-in-time compiled in the browser.

²There has been occasions where there has been minor breaking changes between ECMAScript versions, but these changes happen very rarely and the affected areas are often insignificant.

version the client browser is using. Because of this lack of control over the runtime environment it is crucial that any pre-existing language features don't have breaking changes between versions.

Backwards Compatibility

With new ECMAScript versions comes new features, and it is up to each browser to implement these changes. As we mentioned earlier, we do not transfer a binary to the client browser, we transfer the source code. So when a JavaScript script uses a new ECMAScript feature it is not guaranteed to work with every client browser, since a lot of users might have older browsers installed, or the team behind the browser has not implemented the language feature yet. To deal with this a common practice in JavaScript development is to first transpile the source code before using it in a production environment. This transpilation step takes the source code and transpiles it into an older ECMAScript version. In doing this you ensure that more browsers will be able to run the script. This will rewrite the new language features, and often replace them with a function, called a *polyfill*. You can think of a polyfill as an implementation of a new language feature that you ship with your code. These polyfills help the developer regain some control over the runtime environment on which the code will be run, and ensure that the code will run on almost any browser as expected.

Some popular transpilers for JS to JS transpilation are Webpack and Babel, but you could also use the TypeScript compiler for this.

Node.js

As of the time of writing there are mainly two ways to execute JavaScript. You can run the program in the browser, as it was intended, or you can use a JavaScript runtime that runs on the backend, outside of the browser. Node.js (henceforth simply referred to as Node) is the mainstream solution for the latter. Node is a JavaScript runtime built on the JavaScript engine, V8, used by Chrome. It is independent of the browser and can be run through a *CLI* (Command-Line Interface). One major difference from the browser runtimes is that Node also supplies some libraries for IO, such as access to the file system and the possibility to listen to HTTP requests and WebSocket events. This makes Node a good choice for writing networking applications for instance.

We will be using the Node runtime for our compiler since it gives us access to the file system, as well as enabling the compiler to be executed through a CLI, as is the norm for most compilers. The compiler will still also be available as a library.

2.2.2 What is TypeScript?

TypeScript is a superset of JavaScript. The language builds on JavaScript with the additions of static type definitions [21].

All valid JavaScript programs are also valid TypeScript programs.

Part II

The project

Chapter 3

The Language - PTS

While the majority of the semantics of PTS will be equal to that of PTj, we will have to change some syntax.

3.1 Syntax

For the implementation of PT we need syntax for the following:

- Defining packages (`package` in PTj)
- Defining templates (`template` in PTj)
- Instantiating templates (`inst` in PTj)
- Specifying renaming for an instantiation (`with` in PTj)
- Renaming classes (`=>` in PTj)
- Renaming class attributes (`->` in PTj)
- Additions to classes (`addto` in PTj)

`template`, `addto`, and `inst` are all not in use nor reserved in the ECMAScript standard or in TypeScript, and can therefore be used in Package Template Script without any issues.

The keyword `package` in TS/ES is, as of yet, not in use, however the ECMAScript standard has reserved it for future use. In order to "future proof" our implementation we should avoid using this reserved keyword, as it could have some conflicts with a potential future implementation of packages in ECMAScript. It could also be beneficial to not share the keyword in order to avoid creating confusion between the future ES packages and PT Packages. `module` is also a keyword that could be used to describe a PT package, however this is already used in the ES standard, and should therefore also be avoided in order to avoid confusion. We will therefore use `pack` instead.

Renaming in PTj uses `=>`(fat-arrow) for renaming classes, and `->`(thin-arrow) for renaming class attributes. PTj, for historical purposes, used two

different operators for renaming classes and methods, however in more recent PT implementations, such as [7], a single common operator is used for both. We will do as the latter, and only use a single common operator for renaming. Another reason for rethinking the renaming syntax is the fact that the `=>`(fat-arrow) operator is already in use in arrow functions [1], and reusing it for renaming could potentially produce an ambiguous grammar, or the very least be confusing to the programmer. JavaScript currently supports renaming of destructured attributes using the `:`(colon) operator and aliasing imports using the keyword `as`. We could opt to choose one of these for renaming in PTS as well, however in order to keep the concepts separated, as well as making the syntax more familiar for Package Template users, we will go for the `->`(thin-arrow) operator.

The `with` keyword is currently in use in JavaScript for `with`-statements [11]. With it being a statement, we could still use it and not end up with an ambiguous grammar, however as with previous keywords, we will avoid using it in order to minimize concept confusion. Instead of this we will contain our instantiation renamings inside a block-scope (`{ }`). Field renamings for a class will remain the same as in PTj, being enclosed in parentheses (`()`).

Another change we will make to renaming is to remove the requirement of having to specify the signature of the method being renamed. This was necessary in PTj as Java supports overloading, which means that several methods could have the same name, or a method and a field. Method overloading is not supported in JavaScript/TypeScript, and we do therefore not need this constraint.

3.2 The PTS Grammar

Now that we have made our choices for keywords and operators we can look at the grammar of the language.

PTS is an extension of TypeScript, and the grammar is therefore also an extension of the TypeScript grammar. There is no published official TypeScript grammar (other than interpreting it from the implementation of the TypeScript compiler), however up until recently there used to be a TypeScript specification [13]. This TypeScript specification was deprecated as it proved a to great a task to keep updated with the ever-changing nature of the language. However, most of the essential parts are still the same. The PTS grammar is therefore based on the TypeScript specification, and on the ESTree Specification [15].

In figure 3.1 on the next page we can see the PTS BNF grammar. This is not the full grammar for PTS, as I have only included any additions or changes to the original TypeScript/JavaScript grammars. More specifically the non-terminal `<declaration>` is an extension of the original grammar, where we also include package and template declarations as legal declarations. The productions for non-terminals `<id>`, `<class declaration>`, `<interface declaration>`, and `<class body>` are also from the original grammar.

$\langle \text{declaration} \rangle$	$\models \dots \mid \langle \text{package declaration} \rangle \mid \langle \text{template declaration} \rangle$
$\langle \text{package declaration} \rangle$	$\models \text{pack } \langle \text{id} \rangle \langle \text{PT body} \rangle$
$\langle \text{template declaration} \rangle$	$\models \text{template } \langle \text{id} \rangle \langle \text{PT body} \rangle$
$\langle \text{PT body} \rangle$	$\models \{ \langle \text{PT body decls} \rangle \}$
$\langle \text{PT body decls} \rangle$	$\models \langle \text{PT body decls} \rangle \langle \text{PT body decl} \rangle \mid \lambda$
$\langle \text{PT body decl} \rangle$	$\models \langle \text{inst statement} \rangle \mid \langle \text{addto statement} \rangle \mid$ $\langle \text{class declaration} \rangle \mid \langle \text{interface declaration} \rangle$
$\langle \text{inst statement} \rangle$	$\models \text{inst } \langle \text{id} \rangle \langle \text{inst rename block} \rangle$
$\langle \text{inst rename block} \rangle$	$\models \{ \langle \text{class renamings} \rangle \} \mid \lambda$
$\langle \text{class renamings} \rangle$	$\models \langle \text{class rename} \rangle \mid \langle \text{class rename} \rangle, \langle \text{class renamings} \rangle$
$\langle \text{class rename} \rangle$	$\models \langle \text{rename} \rangle \langle \text{attribute rename block} \rangle$
$\langle \text{attribute rename block} \rangle$	$\models (\langle \text{attribute renamings} \rangle) \mid \lambda$
$\langle \text{attribute renamings} \rangle$	$\models \langle \text{rename} \rangle \mid \langle \text{rename} \rangle, \langle \text{attribute renamings} \rangle$
$\langle \text{rename} \rangle$	$\models \langle \text{id} \rangle \rightarrow \langle \text{id} \rangle$
$\langle \text{addto statement} \rangle$	$\models \text{addto } \langle \text{id} \rangle \langle \text{addto heritage} \rangle \langle \text{class body} \rangle$
$\langle \text{addto heritage} \rangle$	$\models \langle \text{class heritage} \rangle \mid \lambda$

Figure 3.1: BNF grammar for PTS. The non-terminals $\langle \text{declaration} \rangle$, $\langle \text{id} \rangle$, $\langle \text{class declaration} \rangle$, $\langle \text{interface declaration} \rangle$, and $\langle \text{class body} \rangle$ are productions from the TypeScript grammar. The ellipsis in the declaration production means that we extend the TypeScript production with some extra choices.

Legend: Non-terminals are surrounded by $\langle \text{angle brackets} \rangle$. Terminals are in typewriter font. Meta-symbols are in regular font.

3.3 Example programs

Figure [8 on the facing page](#).

```

// PTS
template T {
  class A {
    function f() : string {
      ...
    }
  }
}

pack P {
  inst T { A -> A (f -> g) };
  addto A {
    i : number = 0;
  }
}

// PTj
template T {
  class A {
    String f() {
      ...
    }
  }
}

package P {
  inst T with A => A (f() -> g());
  addto A {
    int i = 0;
  }
}

```

Listing 8: An example program with instantiation, renaming, and addition-classes in PTS vs. PTj

Chapter 4

Planning the Project

Before we start the implementation of our language we first need to do some planning. We know we are going to be creating a programming language, a superset of TypeScript with the addition of Package Templates. However, we might want to look at if creating a superset of TypeScript is the way to go, or if keeping it simple and extending JavaScript is a better call. There are a lot of approaches we can take for implementing our language, so we will have map out the requirements for our approach. Lastly we will have to look at all the different approaches we can take, and discuss the pros and cons of each approach.

This planning phase is crucial for the success of the project, as starting off on the wrong approach for the wrong language would set us back immensely.

4.1 TypeScript vs. JavaScript

When extending TypeScript you might be asking yourself if it is truly necessary, is it better to keep it simple and just extend JavaScript instead? This is something we need to find out before going any further with the planning of our project.

4.1.1 Typechecking templates

One of the requirements of PT is that it should be possible to type-check each template separately. There is no easy way to type-check JavaScript code without executing it and looking for runtime errors. Even if some JavaScript program successfully executes without throwing any errors, we can still not conclude that the program does not contain any type errors. TypeScript on the other hand, with the language being statically typed, we can, at least to a much larger extent, verify if some piece of code is type secure. Because of this trait TypeScript is the better candidate for our language.

Now it should be noted that due to TypeScript's type system being unsound one could argue that this requirement of PT is not met. While this is true it still outperforms JavaScript on this remark, and we will

later in section [6.2.7 on page 50](#) discuss more in-depth to what extent this requirement is met.

4.2 What Do We Need?

There are a lot of approaches one can take when working with TypeScript, however due to the nature of this project there are some restrictions we have to abide by. Our approach should allow the following:

- The ability to add custom syntax (access to the tokenizer / parser)
- Enable us to do semantic analysis.

In addition to these we would also like to look for some other desirable traits for our implementation:

- Loosely coupled implementation (So that new versions of typescript not necessarily breaks our implementation).

4.3 Choosing the right approach

Before jumping into a project of this magnitude it is important to find out what approach to use. The goal of this project is to extend TypeScript with the Package Templates language mechanism, this could be achieved by one of the following methods:

- Making a fork of the TypeScript compiler
- Making a preprocessor for the TypeScript compiler
- Making a compiler plugin / transform
- Making a custom compiler from scratch

4.3.1 Preprocessor for the TypeScript Compiler

More work than ex plugin / transformer.

4.3.2 TypeScript Compiler Plugin / Transform

At the time of writing the official TypeScript compiler does not support compile time plugins. The plugins for the TypeScript compiler is, as the TypeScript compiler wiki specifies, "for changing the editing experience only" [12]. However, there are alternatives that do enable compile time plugins / transformers;

- ts-loader [22], for the webpack ecosystem
- Awesome Typescript Loader [17], for the webpack ecosystem. Deprecated

- ts-node [23], REPL / runtime
- ttypescript [5], TypeScript tool TODO: Les mer på dette

Unfortunately ts-loader, Awesome Typescript Loader and ts-node does not support adding custom syntax, as it only transforms the AST produced by the TypeScript compiler. Because of this they are not a viable option for our use-case and will therefore be discarded.

4.3.3 Babel plugin

Babel isn't strictly for TypeScript, but for JavaScript as a whole, however we could write our plugin to be dependent on the TypeScript transformation plugin.

Making a Babel plugin will make it very accessible as most web-projects use Babel, and the upkeep is cheap, as plugins are loosely coupled with the core.

In order for a Babel plugin to support custom syntax it has to provide a custom parser, a fork of the Babel parser. Through this we can extend the TypeScript syntax with our syntax for PT. This is all hidden away from the user, as this custom parser is a dependency of our Babel plugin.

Seeing as we have to make a fork of the parser in order to solve our problem, the upkeep will not be as cheap as first anticipated. However, being able to have most of the logic loosely coupled with the compiler core it will still make it easier to keep updated than through a fork of the TypeScript compiler.

4.3.4 TypeScript Compiler Fork

Possible, however not as accessible as other alternatives and will make upkeep expensive.

The TypeScript compiler is a monolith. It has about 2.5 million lines of code, and therefore has a quite steep learning curve to get into. If we were to go with this route it would be quite hard to keep up with the TypeScript updates, as updates to the compiler might break our implementation. However, as we have seen, going the plugin / transform route also requires us to fork the underlying compiler and make changes to it, however with the majority of the implementation being loosely coupled it would still make it easier to keep up-to-date. That being said it will probably be a lot easier to do semantic analysis in a fork of the TypeScript compiler vs in a plugin / transform.

Chapter 5

Implementation

In this chapter we are going to look at the implementation for our compiler for PTS, as described in [chapter 3 on page 19](#). Before looking at the implementation we will first be discussing the methodology used during development.

5.1 Methodology

When tackling a project of this magnitude it is important to have a proper methodology for development. During the development phase of this project I have had a strong focus on using agile techniques, where I have filled the role as both product owner and developer. This agile software development has aided me in discovering new requirements as the project moves forward, and re-adjusting to these new requirements. I have actively used a Kanban board throughout development to help keep track of tasks and goals.

The compiler was made in an iterative manner. For each iteration I would start off by implementing a new feature, and then put on the product owner hat and test out the compiler. While working as product owner I try to understand how I would like to use the language and what requirements I have for the language. This often leads to re-adjusting the requirements.

I started off by creating a rough MVP (Minimum Viable Product), only implementing the most basic functionality, which comprised declaration of packages/templates and simple instantiation. This MVP made me understand the project and requirements better, and also gave the project some new requirements. After the initial iteration I decided to adopt a test-driven development approach. I made tests for the features I had already implemented and then continued to make tests for the next functionality goal. This was done in order to gain more confidence in the compiler, as well as helping me spot any erroneous code earlier rather than later, which makes fixing it less costly. All of this resulted in a better development cycle, making refactoring and implementation of new features a breeze. When adding new features or refactoring some tests will undoubtedly fail, and before moving on I made sure that all the tests were passing again.

Figure 5.1: Overview of the compiler

5.2 Compiler Architecture

Our compiler consists of the following parts:

- Lexing and parsing
- Parse tree transformation
- Type checking packages/templates
- Code generation

An overview of our architecture can be seen in figure 5.1. The first part of the compiler, namely the lexing and parsing will take a source file and transform it into a parse tree. Our compiler will then take this parse tree and transform it into a simpler abstract syntax tree (AST). This AST will then be used to perform the PT transformations. We will then use this AST to close any open packages and templates, and finally use the transformed tree for code generation. After all packages and templates have been closed we can type-check each individual package/template to validate the type-safety of our program. Given a valid type-safe program we can then move on to code generation. The target language for our code generation will mainly be TypeScript, however we will also offer to transpile the TypeScript into JavaScript.

5.3 Lexer and Parser

5.3.1 Parser Generator

There are a lot of parser generators out there, but there is no one-size-fits-all solution. In order to navigate through the sea of options we need to set some requirements in terms of functionality, so that we can more easily find the right tool for the task.

As we talked about in section 4.2 on page 26, we set ourselves the goal to find an approach that would allow us to create an implementation that

was loosely coupled with TypeScript. TypeScript is a large language that is constantly updated, and is getting new features fairly often. Because of this one of the requirements for our choice of parser generator is the possibility for extending grammars. This is important because we want to keep our grammar loosely coupled with the TypeScript grammar, and don't want to be forced to rewrite the entire TypeScript grammar, as well as keeping it up-to-date.

Because our language will be extending TypeScript we would like to utilize the TypeScript compiler as much as we can. The TypeScript compiler will help us perform the type-checking for our compiler, as well as producing JavaScript output. Therefore we need to be able to interact with the TypeScript compiler somehow. The TypeScript compiler has two main interfaces for interaction, through the command-line interface or using the compiler API. Optimally we would like to use the compiler API as this is the easiest way for us to perform type-checking and compilation. The catch is however that the only supported languages for the compiler API is JavaScript and TypeScript. Therefore a desired attribute for our choice of parser generator is that it offers a runtime library in either JavaScript or TypeScript, so that all of our implementation can be done in the same language, and not have to work with command-line interfaces programmatically.

ANTLR4

ANTLR, ANother Tool for Language Recognition, is a very powerful and versatile tool, used by many, such as Twitter for query parsing in their search engine [18].

ANTLR supports extending grammars, or more specifically importing them. Importing a grammar works much like a "smart include". It will include all rules that are not already defined in the grammar. Through this you can extend a grammar with new rules or replacing them. It does not however support extending rules, as in referencing the imported rule while overriding [18]. This isn't a major issue however as you could easily rewrite the rule with the additions.

The only supported runtime library in ANTLR is in Java. This does not mean that you won't be able to use it in any other language, as you could simply invoke the runtime library through command line, however it is worth keeping in mind.

Overall ANTLR seems like a good option for our project, but the lack of a runtime library in TypeScript is a hurdle we would rather get a round if we can.

Bison

Bison is a general-purpose parser generator. It is one of many successors to Yacc, and is upwards compatible with Yacc [6].

Bison does not support extending grammars. The tool works on a single grammar file and produces a C/C++ program. There is a possibility to

include files, like with any other C/C++ program, in the grammar files prologue, however this will not allow us to include another grammar, as it only inserts the prologue into the generated parser. In order to extend a grammar we would have to change the produced parser to include some extra rules. Although this could possibly be automated by a script, it seems too hacky of a solution to consider.

On top of this Bison does not have a runtime library in JavaScript/-TypeScript. There do exist some ports/clones of Bison for JavaScript, such as [Jison](#) and [Jacob](#), however to my knowledge these also lack the functionality of extending grammars.

Tree-sitter

[Tree-sitter](#) is a fairly new parser generator tool, compared to the others in this list. It aims to be general, fast, robust and dependency-free [4]. The tool has been garnering a lot of traction the last couple of years, and is being used by Github, VS Code and Atom to name a few. It has mainly been used in language servers and syntax highlighting, however it should still work fine for our compiler since it does produce a parse tree.

Although it isn't a documented feature, Tree-sitter does allow for extending grammars. Extending a grammar works much like in ANTLR, where you get almost a superclass relation to the grammar. One difference from ANTLR though is that it does allow for referencing the grammar we are extending during rule overriding. This makes it easier and more robust to extend rules than in ANTLR.

Tree-sitter also has a runtime library for TypeScript, which makes it easier for us to use it in our implementation than the previous candidates.

Another cherry on top is that Tree-sitter is becoming one of the mainstream ways of syntax highlighting in modern editors and IDEs, which means that we could utilize the same grammar to get syntax highlighting for our language.

All this makes Tree-sitter stand out as the best candidate for our project.

Implementing Our Grammar in Tree-sitter

Tree-sitter uses the term rule instead of production, and I will therefore also refer to productions as rules here.

Extending a grammar in Tree-sitter works much like extending a class in an object-oriented language. A "sub grammar" inherits all the rules from the "super grammar", so an empty ruleset would effectively work the same as the super grammar. Just like most object-oriented languages have access to the super class, we also have access to the super grammar in Tree-sitter. All of this enables us to add, override, and extend rules in an existing grammar, all while staying loosely coupled with the super grammar. By extending the grammar, and not forking it, we are able to simply update our dependency on the TypeScript grammar, minimizing the possibility for conflicts.

```
_declaration: ($, previous) =>
  choice(
    previous,
    $.template_declaration,
    $.package_declaration
  )
```

Listing 9: Snippet from the PTS grammar, where we override the `_declaration` rule from the TypeScript grammar, and adding two additional declarations.

As mentioned, Tree-sitter allows for referencing the super grammar during rule overriding, effectively making it possible to combine the old rule and the new. A good example of overriding and combining rules can be found in the grammar of PTS, see listing 9, where we override the `_declaration` rule from the TypeScript grammar, to include the possibility for package and template declarations.

5.4 Transforming Parse Tree to AST

5.4.1 The AST Nodes

Tree-sitter is a parser-generator written in Rust and C. Fortunately for us we can still use tree-sitter in Node, due to Node supporting native addons¹. Native addons in Node are fairly new, and at the time of writing the tree-sitter Node bindings are still using the older unstable *nan* (Native Abstractions for Node) instead of the newer and more stable *Node-API*. For the most part it does work, however I did meet some difficulties with the produced parse tree, more specifically the spread operator was not behaving properly on the native produced objects. To get around this we will be walking through the parse tree and produce an AST. What this means in practice is that we are going to be ignoring some parsing specific properties. One of the changes we are going to make is that we are going to ignore if a node is named or unnamed, we will be keeping all nodes. This will help us later in code generation.

For each AST node we picked out the following properties from the parse tree:

- Node type
- Text
- Children

The node type is a string representing the rule which produced the node. An AST node with a node type value of `"class_declaration"` for instance is a class declaration node.

¹Node native addons are dynamically-linked shared objects written in C++ [16].

The text field of an AST node contains the textual representation/code for the node and its children. A class declaration node for instance would of course contain the class declaration (`"class A extend B {"`), but also the entire body of the class. This text field is really only useful for leaf nodes, as this would for instance contain the value of a number, string, etc.

Finally, the children field is, as the name would suggest, a list of all the children of the node. For a class declaration node this would contain a leaf node containing the keyword `class`, a type identifier for the class name, and the class body. Optionally it could also contain a class heritage node, which again contains either an extends clause, an implements clause or both.

We could have also opted to get the start position and end position of each node, so that we could use this to produce better error messages. This was however not a priority in this thesis.

5.4.2 Transforming

I chose to do the transforming immutable, and in order to do this we have to traverse the parse tree depth first and create nodes postfix. Tree-sitter provides pretty nice functionality for traversing the parse tree through cursors. With a tree cursor we are able to go to the parent, siblings, and children easily. Using this we visit each node and produce an AST node as described in the section above.

5.5 Closing Templates

The task of closing open packages and templates is what most of the implementation is focused around. It is the task of performing the declared instantiations and altering the declared classes through `addto`-statements. This step is crucial as it will make each package/template a valid TypeScript program and make the program ready for code generation.

For instantiations without renaming the task is fairly simple. We merely have to find the referenced template, and replace the instantiation statement with the body of said template. Renaming on the other hand requires a bit more work.

In order to perform renaming on an instantiation we will have to perform the following tasks.

1. Create a scope for the template body, and give all nodes of the body access to this scope
2. Find all identifiers, member expressions, class declarations, etc., and replace them with *reference nodes*²
3. Perform the rename.

²Reference nodes are AST nodes that contain a pointer to the class or attribute they are supposed to represent. This makes the task of renaming easier as we only have to worry about changing the name in one place. We will go into more detail about this in [section 5.5.2 on the facing page](#).

4. Transform the scoped AST with reference nodes back to the original AST.
5. Merge class declarations and apply addto statements.

If the template body is also open we would have to close it as well. We want to close the nested templates before closing the upper templates, as renaming at the top level should affect all members from the nested instantiations.

Finally, once all templates have been closed we will have to perform class merging and apply any additions to classes.

In order to get a better understanding of this we will go through each step of closing a template in more detail.

5.5.1 Scoping

This step of closing templates works on the body of a copy of the instantiated template. In order to be able to rename classes and class attributes we first need to create correct scopes in which the renaming can be applied to. We start of with a list of normal AST nodes and will transform these nodes into nodes that has a reference to the scope they are part of.

Scopes in the compiler mainly consists of three different classes. The `Scope`, `Variable`, and `Class` classes.

The `Scope` class is essentially a symbol table that optionally extends a parent scope. A scope without a reference to a parent scope is the root scope. The symbol table is implemented as a map from the original attribute or class name, to a reference to either `Variable` or `Class` instance. Looking up symbols in the symbol table will always start in the called scope, and work its way upwards until we reach the root scope. This allows us to correctly handle shadowed variables.

The `Variable` class is a representation for class attributes. The class contains the name of the attribute.

For creating scopes I chose the following node types for "making new scopes".

- | | |
|--------------------------------|---------------------------------|
| • <code>class_body</code> | • <code>for_in_statement</code> |
| • <code>statement_block</code> | • <code>while_statement</code> |
| • <code>enum_body</code> | • <code>do_statement</code> |
| • <code>if_statement</code> | • <code>try_statement</code> |
| • <code>else_statement</code> | • <code>with_statement</code> |
| • <code>for_statement</code> | |

5.5.2 Transforming Nodes to References

Transforming nodes into references mainly consists of two steps.

- Transform declarations
- Transform references

Transform Declarations

The task of transforming declarations requires several passes through the AST. This is because in order to register some declarations we need to have others registered. To understand this we can look at the difference between the first and second pass.

During the first pass through the AST we register and transform all class declarations. Now for the second pass we register class heritage. The second pass needs to update the Class instances from the first pass with what class they are extending. If we try to do this in a single pass we would have to register classes

Transform References

5.5.3 Performing the Rename

With all declarations and references transformed into reference nodes we can now perform the rename. For each class rename we can simply lookup the old class name in the root scope and change the reference to the new class name. For class attribute renames we do the same just for the enclosing classes scope.

5.5.4 Going back to the original AST

reference -> original with new names remove scope

5.5.5 Merging Class Declarations

Check if can be merged, non overlapping members. Override and merge addto Preserve hierarchy

5.6 Type-checking of Templates

After the previous step we have a program where all packages and templates are closed, meaning that the bodies of these should contain plain TypeScript. Because of this we can relatively easily type-check these by using the TypeScript compiler and its compiler API. In order for us to type-check our packages/templates we will have to transform the bodies of the packages/templates into a textual format. This will be done by applying our code generation implementation, which we will discuss in [section 5.7 on the next page](#), to the body of the package/template we are currently working on. Running code generation on the package/template body will give us a TypeScript program. This program can then be passed on to the TypeScript compiler. We will make the TypeScript compiler transpile the

program to JavaScript without emitting any output. This will effectively type-check the program.

If the TypeScript compiler throws any errors we can log this for the user of our compiler to fix, and give which package/template this error was found. If no errors were thrown we have a type-safe package/template, and we can then proceed to the next step in our compilation.

5.7 Code Generation

After performing these steps we can finally produce the output. Producing TypeScript output is a pretty simple task. By traversing the AST we can concatenate the text from each leaf node with whitespace between each leaf node's resulting textual representation. This will produce quite ugly, unformatted code, but as long as the contents of the closed packages and templates are valid typescript programs this will also produce a valid typescript program. In order to make it more readable we perform an extra step before writing the output to the specified file, a formatting step. There are a lot of TypeScript formatters out there, but we will be using *Prettier*³ for our implementation as it is relatively simple to use. Running our produced source code through the Prettier formatter produces a nicely formatted, readable output.

The TypeScript output is probably the best target for understanding what the PT mechanism does, however it might not be the best output for production use. Since the only officially supported language for the web is JavaScript we will also be implementing this as a target for code generation. This is fortunately also a relatively simple task, as we already depend on the TypeScript compiler, and since we are able to produce TypeScript source code, we can use this to produce JavaScript output.

5.8 Notes on Performance

Very slow compiler/PP because of the chosen implementation, with tree traverser for every step.

5.9 Testing

Testing has been an essential part throughout the development of the compiler. After the initial prototype of the compiler was running I continued onward with test driven development. This allows me to write up tests for all the features of the language, and run them concurrently as I make the changes to the implementation.

The cycle

³A code formatter for the web ecosystem. See <https://prettier.io/>.

```

=====
Closed template declaration
=====

template T {
    class A {
        i = 0;
    }
}

---
(program
  (template_declaration
    name: (identifier)
    body: (package_template_body
      (class_declaration
        name: (type_identifier)
        body: (class_body
          (public_field_definition
            name: (property_identifier)
            value: (number)))))))

```

Listing 10: Example of tree-sitter grammar test

5.9.1 Lexer and Parser

Tree-sitter tests are simple .txt files split up into three sections, the name of the test, the code that should be parsed, and the expected parse tree in *S-expressions*⁴.

5.9.2 Transpiler

Started with jest, and used some time to get it to work with typescript files, however had to switch because jest doesn't handle native libraries (tree-sitter) too well. It requires the same native library several times, making the wrapping around the native program to break.

⁴S-expressions are textual representations for tree-structured data. See [20] for additional information and examples

Chapter 6

Does PTS Fulfill The Requirements of PT?

This thesis is concerned about implementing Package Templates in TypeScript. However, in order to determine to what degree we have actually implemented PT or just created something that looks like it, we have to understand what the requirements of PT are, and if we are meeting those requirements. We will therefore in this chapter look at the requirements as described in [9]. After getting an understanding of the requirements we are going to look at how our implementation holds up to them.

6.1 The Requirements of PT

In [9] the authors discuss requirements of a desired language mechanism for re-use and adaptation through collections of classes. They then present a proposal for Package Templates, which to a large extent fulfills all the desired requirements. These requirements can therefore be used to evaluate our implementation and determine whether our implementation can be classified as a valid implementation of Package Templates.

The requirements presented in the paper were the following:

- Parallel extension
- Hierarchy preservation
- Renaming
- Multiple uses
- Type parameterization
- Class merging
- Collection-level type-checking

In order to get a better understanding of what these requirements entail we will have to dive a bit deeper into each requirement.

6.1.1 Parallel Extension

The parallel extension requirement is about making additions to classes in a package/template, and being able to make use of them in the same collection. What this means is that if we are making additions to a class,

```
template T {  
    class A {  
        ...  
    }  
  
    class B {  
        A a = new A();  
        ...  
    }  
}  
  
package P {  
    inst T;  
  
    addto A {  
        void someMethod() {  
            ...  
        }  
    }  
  
    addto B {  
        void someOtherMethod() {  
            a.someMethod();  
        }  
    }  
}
```

Listing 11: Example of parallel extension in PTj. Here we make additions to both A and B in our instantiation in package P, and we are able to reference the additions done to A in our addition to B. This is done without the need to cast A, as if the additions were present at the time of declaration.

then we should be able to reference these additions in a declaration or in an addition to a separate class within the same package/template, without needing to cast it. We can see an example of this in listing 11, where an addition to class B is referencing the added method of class A. The order of additions does not affect the parallel extension. We could just as easily switched the positions of the additions around in this example.

6.1.2 Hierarchy Preservation

PT should never break the inheritance hierarchy of its contents. If we have a template with classes A and B, and class B is a subclass of class A, then this relation should not be affected by any additions or merges done to either of the classes. That is if we make additions to class B it should still be a subclass of class A, and any additions made to class A should be inherited to class B. Even if we make additions to both class A and B, then B with

additions should still be a subclass of class A with additions.

6.1.3 Renaming

The renaming requirement states that PT should enable us to rename the names of any class, and its attributes, so that they better fit their use case.

6.1.4 Multiple Uses

PT should be allow us to use packages/templates multiple times for different purposes in the same program, and any additions or renamings should not affect any of the other uses. Each use should be kept independent of each other. This is an important requirement of PT as when we create a package or a template it is often designed to be reused. An example of this is the graph template we created in [listing 3 on page 8](#). Here we bundled the minimal needed classes in order to have a working implementation for graphs. We then used this graph implementation to model a road systems, however we might later also want to reuse the graph implementation for modelling the sewer systems of each city, and this should not be affected by any changes we made to the graph template for our road system.

6.1.5 Type Parameterization

The requirement of type parameterization of templates works similar to how type parameterization for classes works in Java. Type parameterization in Java enables the programmer to assume the existence of a class during declaration, and the class can later be given at the time of instantiation. Type parameters in Java can have a constraint that it must extend another class. Similarly, type parameterization in PT also enables the programmer to assume the existence of a class, however here the type parameter is accessible to the whole template. PT type parameters can also be constrained, however in PT type constraining uses structural typing instead of nominal typing. What this means is that instead of declaring what the type parameter must extend it instead declares what structure the type parameter must conform to.

In [listing 12 on the following page](#) we see an example of how type parameterization can be used to implement a list. This example might not look too different from what you would do with type parameterization in Java, however having the type parameter at the template level does have some advantages. One advantage of having the type parameter at template level is that you don't need to specify the actual parameter again after the instantiation. At instantiation of the `ListsOf` template we can give i.e. a `Person` class, containing some information about a persons name, date of birth, etc., as the actual parameter, and then we would not have to keep specifying the actual parameter for every reference. Another advantage of using type parameters at the template level is that the type parameter can be used by all classes in the template. If we wanted to implement this in

```

template ListsOf<E> {
    class List {
        AuxElem first, last;
        void insertAsLast(E e) { ... }
        E removeFirst() { ... }
    }
    class AuxElem {
        AuxElem next;
        E e; // Reference to the real element
    }
}

```

Listing 12: Example from [9] where type parameterization is used to create a list implementation.

Java we would either have to have type parameters for both classes, or the `AuxElem` class would need to be an inner class of the `List` class.

6.1.6 Class Merging

PT should allow for merge two or more classes. When merging classes the result should be a union of their attributes. If we merge two classes A and B, it should be possible to reach all B attributes from an A-variable, and vice versa.

6.1.7 Collection-Level Type-Checking

The final requirement is collection-level type-checking. This requirement is there to ensure that each separate package/template can be independently type-checked. By having the possibility to type-check each package/template we can also verify that the produced program is also type-safe, as long as the instantiation is conflict-free.

6.2 PTS' Implementation of the Requirements

With a proper understanding of the requirements of PT we can examine our implementation and see whether our implementation fulfills these requirements. For each requirement we will be looking at a program in PTS which showcases the requirements, and the resulting program after compilation.

6.2.1 Parallel Extension

In order for our implementation to fulfill this requirement it will have to be able to reference additions to a class in another addition in the same package/template. We can check if this is possible by creating a simple program, as seen in listing 13 on page 46, and see if this results in a valid

TypeScript program with the intended semantics and correct bindings. Our PTS program consists of a template *T* with two classes *A* and *B*, and a package *P* which makes additions to both classes. The addition to class *A* simply adds another field, *j*, to the class, while the addition to class *B* adds a method to the class which references both the old attribute of class *A* as well as the new addition. The program successfully compiles, and the resulting TypeScript program can be seen at the bottom of the listing.

Now we see that it does work for the program above, so it would seem that the basic mechanism for parallel extensions does work. However, to be completely certain that it will work for all programs we are going to have to investigate this a bit further. To understand how this requirement can be fulfilled it is important to understand how the requirement could fail to be fulfilled. A failure to fulfill the requirement would be that making additions in parallel would fail to compile. Given a syntactically legal program the only ways for this to fail during compilation would be due to a semantic error. The legal reasons for an addition to fail would be if we are trying to make additions to a class which doesn't exist, or if we are trying to reference attributes in a class that does not exist. Both of these should fail, and in our compiler will fail.

The first legal reason where our compiler should fail is when we are making additions to a non-existent class. This will be caught in the class merging part of our compiler. In the class merging part of the implementation the compiler will group all classes and additions by name. If there is a group with only additions then it will fail, as there is no class to make additions to.

The second legal reason is when we are trying to reference non-existent attributes in a class. An example of this can be seen in [listing 14 on page 47](#). This example will fail during the type-checking of our packages/templates, as discussed in [5.6 on page 36](#). Instead of trying to examine the class *A* for an attribute *h*, and maybe not finding it as it might be in a later instantiation, we will assume that the addition is valid and perform the addition to the class. When we later have performed any further instantiations and additions we will run a type-check on the templates/packages which will pick the error up.

Now that we understand when it should fail let's look at some scenarios where it should not fail. We do not want it to fail compilation if we have a valid parallel extension. One such way it could fail is if we tried to check if the addition contains any invalid references or type errors. This could commonly happen if we are trying to check the addition's references to the declared class. However if not implemented properly this might fail as there might be several declarations that are going to be merged, including additions. As we discussed previously we are avoiding this from happening by assuming that the addition is valid, and waiting until all merging has been performed and then type-checking the program afterwards. This has the downside of making it harder to give meaningful error messages when an error is made by the programmer, however we can assure ourselves that we do not wrongly fail compilation.

```
// PTS
template T {
  class A {
    i = 1;
  }

  class B {
    a = new A();
    x = 1;
  }
}

pack P {
  inst T;
  addto A {
    j = 1;
  }

  addto B {
    function f() {
      return this.a.i + this.a.j;
    }
  }
}

// Resulting program
class A {
  i = 1;
  j = 1;
}

class B {
  a = new A();
  x = 1;
  function f() {
    return this.a.i + this.a.j;
  }
}
```

Listing 13: A program showcasing parallel extension in PTS, and the resulting program in TypeScript at the bottom.

```
template T {
  class A {
    function f() {
      return 1;
    }
  }
}

package P {
  inst T;
  addto A {
    function g() {
      this.h();
    }
  }
}
```

Listing 14: An example showing a program that should fail during compilation, where we are trying to reference a non-existent attribute, `h`, in an addition to class `A`.

6.2.2 Hierarchy Preservation

In order to fulfill the hierarchy preservation requirement we have to preserve all super-/subclass relations after additions and merges have been applied. Listing 15 on the following page shows a program, and the resulting TypeScript program after compilation, which fulfills the requirement of hierarchy preservation. This one example certainly fulfills the requirement as class `B` is still a subclass to class `A` after both a merge and an addition is made to `B`. As we talked about briefly in section 5.5.5 on page 36 when we merge classes we make sure to also merge their class signatures. This means that we might end up with instances where we are extending multiple classes, however this will then be picked up in the type-checking stage of the compiler. If we had not merged class declarations, and just stuck with a random class declarations in the group of classes that should be merged for instance, we could have ended up breaking the inheritance hierarchy in the aforementioned listing, as we could have ended up with class `C`'s declaration, which does not have a superclass. Because of this we can with confidence say that we have fulfilled the requirement of hierarchy preservation.

6.2.3 Renaming

This requirement

```
// PTS
template T1 {
  class A {
    i = 0;
  }

  class B extends A {
    f() {
      return this.i;
    }
  }
}

template T2 {
  class C {
    j = 0;
  }
}

package P {
  inst T1;
  inst T2 { C -> B };
  addto B {
    k = 0;
  }
}

// Resulting program
class A {
  i = 0;
}

class B extends A {
  f() {
    return this.i;
  }
  j = 0;
  k = 0;
}
```

Listing 15: Example showcasing a program where the super-/subclass relation between classes A and B is preserved after additions and class merging have been applied. We can see the resulting TypeScript program at the bottom of the listing, where the semantics are as expected.

```
// PTS
template T {
    class A {
        i = 0;
    }
}

pack P {
    inst T { A -> B (i -> j) };
    inst T;
    inst T { A -> A (i -> x) };
}

// Resulting program
class B {
    j = 0;
}

class A {
    i = 0;
    x = 0;
}
```

Listing 16: A program showcasing multiple uses in PTS, and the resulting program in TypeScript at the bottom.

6.2.4 Multiple Uses

In order for this requirement to be fulfilled we should be able to re-use a template several times, with different renamings and additions while the different instantiations stay independent of each other. This was something I paid extra attention to during implementation, not just to fulfill the requirement, but to avoid bugs. I solved this by making sure that while transforming the AST this would be done in an immutable fashion. In order to test this we will be creating a simple program where we instantiate the same template more than once and see if the resulting program is as expected. The program can be seen in listing 16. The program comprises a template `T` with a single class, `A`, with an attribute `i`. This template will then be instantiated three times, where we first will be renaming the class and field, then instantiate without renaming, and finally instantiate it with just an attribute renaming. The expected program should have two classes, one class `B`, with an attribute `j`, and a class `A` where the two bottom instantiations should have created a merged class with attributes `i` and `x`. We can see from the resulting program after a successful compilation that this is as expected.

6.2.5 Type Parameterization

The type parameterization requirement is something the implementation does not fulfill. This was not implemented due to it being down prioritized. There is only so much time available during the span of a master thesis, and I chose to rather look at how the core of PT would fit into a structurally language like TypeScript, rather than on making sure it would be a fully fleshed out implementation of PT. Another reason for avoiding this is that much of Type Parameterization can be achieved through merging and renaming.

6.2.6 Class Merging

6.2.7 Collection-level Type-checking

Chapter 7

Difference between PTS and PTj

7.1 Nominal vs. Structural Typing

One of the most notable differences between PTS and PTj are the underlying languages' type systems. PTS, as an extension of TypeScript, has structural typing, while PTj on the other hand, an extension of Java, has nominal typing.

Nominal and structural are two major categories of type systems. Nominal is defined as "being something in name only, and not in reality" in the Oxford dictionary. Nominal types are as the name suggest, types in name only, and not in the structure of the object. They are the norm in mainstream programming languages, such as Java, C, and C++. A type could be `A` or `Tree`, and checking whether an object conforms to a type restriction, is to check that the type restriction is referring to the same named type, or a subtype. Structural types on the other hand are not tied to the name of the type, but to the structure of the object. These are not as common in mainstream programming languages, but are very prominent in research literature. However, in more recent (mainstream) programming languages, such as Go, TypeScript and Julia (at least for implicit typing), structural typing is becoming more and more common. A type in a structurally typed programming language is often defined as a record, and could for example be `{ name: string }`.

In listing [17 on the next page](#) we can see an example of a nominally typed program in a Java-like language. Here `B` is a subtype of `A`, while `C` is not. This is due to nominally typed programs having the requirement of explicitly naming its subtype relations, through e.g. a subclass-relation. Because of this we can see that at the bottom of the listing the first two statements pass, since both `A` and `B` are of type `A`, while the last statement fails (typically at compile time), as `C` is not of type `A`.

In listing [18 on page 53](#) we see a structurally typed program. This program also has the exact same declarations as in listing [17 on the next page](#), that is classes `A`, `B`, and `C` and the function `g`. In this program both type `B` and type `C` are a subtype of type `A`, since they both contain all members

```
// Given the following class definitions for A, B and C:
class A {
    void f() {
        ...
    }
}

class B extends A {
    ...
}

class C {
    void f() {
        ...
    }
}

// And a consumer with the following type:
void g(A a) { ... }

// Would result in the following
g(new A()); // Ok
g(new B()); // Ok
g(new C()); // Error, C not of type A
```

Listing 17: Example of a nominally typed program in a Java-like language

of type A. Not necessarily the same implementation as in class A, but the same types as in type A. This is one of the sole differences between nominal and structural typing, types can conform to other types without having to explicitly state that they should. Type C is an example of this, while it does not have a subclass relation to class A, nor implement any common interface, it still conforms to the type of A. The result of this is that all three usages of function g are valid in a structural type system, while consuming C was illegal in the nominal example.

7.1.1 Advantages of Nominal Types

Subtypes

In nominal type systems it is trivial to check if a type is a subtype of another, as this has to be explicitly stated, while in structural type systems this has to be structurally checked, by checking that all members of the super type, are also present in the subtype. Because of this each subtype relation only has to be checked once for each type, which makes it easier to make a more performant type checker for nominal type systems. However, it is also possible to achieve similar performance in structurally typed languages

```
// Given the same class definitions and
// the same consumer as in the example above.
// Would result in the following
g(new A()); // Ok
g(new B()); // Ok
g(new C()); // Ok, because C is structurally equal to A
```

Listing 18: Example of a structurally typed program in a Java-like language

```
// Given class A
class A {
    void f() { ... }
}

// A subtype, B, in nominal typing
class B extends A { ... }

// A subtype, C, in structural typing
class C {
    void f() { ... }
    int g() { ... }
}
```

Listing 19: Example of subtype relations in nominal and structural typing, in a Java-like language. In the example of the nominal subtype we have to explicitly state the subtype relation, while in the structural subtype example the subtype relation is inferred from the common attributes.

through some clever representation techniques [19]. We can see an example of subtype relations in both nominal and structural type systems, in a Java-like language, in listing 19. It is important to note that even though C is a *subtype* of A in a structural language, it is not a *subclass* of A.

Runtime Type Checking

Often runtime-objects in nominally typed languages are tagged with the types (a pointer to the "type") of the object. This makes it cheap and easy to do runtime type checks, like in upcasting or doing a `instanceof` check in Java. It is also easier to check sub-type relations in nominal type systems, even though you might still have to do a structural comparison, you only have to perform this once per type [19].

7.1.2 Advantages of Structural Types

Tidier and More Elegant

Structural types carry with it all the information needed to understand its meaning. This is often seen as an advantage over nominal typing as the programmer arguably only has to look at the type to understand it, while in nominal typing you would often have to look at the implementation or documentation to understand the type, as the type itself is part of a global collection of names [19].

More General Functions/Classes

Malayeri and Aldrich performed a study (see [10]) on the usefulness of structural subtyping. The study was mainly focused around two characteristics of nominally-typed programs that would indicate that they would benefit from a structurally typed program. The first characteristic was that a program is systematically making use of a subset of methods of a type, in which there is no nominal type corresponding to the subset. The second characteristic was that two different classes might have methods which are equal in name and perform the same operation, but are not contained in a common nominal supertype. 29 open-source Java projects were examined for these characteristics.

For the first characteristic the authors ran structural type inference over the projects and found that on average the inferred structural type consisted of 3.5 methods, while the nominal types consisted of 37.8 methods. While for the second characteristic the authors looked for types with more than one common methods and found that every 2.9 classes would have a common method without a common nominal supertype. We can see that from both of these characteristics that the projects could have benefited from a structural type system, as this would make the programs more generalized, and could therefore support easier re-use of code.

7.1.3 Disadvantage of Structural Type Systems

It is worth noting that the advantage of types conforming to each other without explicitly stating it in structural type systems can also be a disadvantage. Structurally written programs can be prone to *spurious subsumption*, that is consuming a structurally equal type where it should not be consumed. An example of this can be seen in listing [20 on the next page](#).

7.1.4 What Difference Does This Make For PT?

We are not going to go further into comparing nominal and structural type systems and "crown a winner", as there are a lot useful scenarios for both nominal and structural type systems. We will instead look more closely into how a structural type system fits into PT, and what differences this makes to the features, and constraints, of this language mechanism.

```
function double(o: {calculate: () => number}) {
    return o.calculate() * 2
}

const vector = {
    x: 2,
    y: 3,
    calculate: () => 4
}

const unintended = {
    calculate: () => {
        doSomeSideEffect();
        return 1;
    }
}
```

Listing 20: Example of spurious subsumption in TypeScript. Here the function `double` will consume an object that has a `calculate` attribute. The intended use is to consume something that does a calculation on the object and returns a number which will be doubled, while the unintended use example in this case does some unexpected side-effect and returns a number as a status code. The unintended object can be consumed by the `double` function as it conforms to the signature of the function, while in a nominally typed system this can be avoided to a much larger extent.

7.1.5 Which Better Fits PT?

With the addition of required types in PT the language mechanism now has to utilize structural typing, independent of the underlying language's type system. Using structural typing was seen as a necessity for required types as this would give the mechanism the its required flexibility. One could therefore argue that a structural type system is a better fit for Package Templates as it would remove the confusion of dealing with two different styles of typing in a single program, and make the language mechanism feel more like a first class citizen of the host language.

Another advantage for having structural typing for PT is that it can help strengthen one of the main concepts of Package Templates, namely re-use. As we learned from the study of Malayeri and Aldrich, structural typing can make programs more general which makes them more prone to re-use.

However, there are also some quite significant problems with having PT in a structural language. Renaming is especially something that might not fit nicely into a structurally typed language. In [listing 21 on the facing page](#) we see an example of a program that breaks after renaming an attribute. The renaming resulted in class `Consumable` no longer conforming to the signature of function `f` in class `Consumer`. PT does not support changing the signature of functions so there is no way for us to be able to make the `Consumable` class conform. In order to avoid running into this problem we might consider disallowing inline type declaration. This would force [listing 21 on the next page](#) to give an interface as the type for the formal parameter, `consumable`. We could then also rename the members of the interface in order to once again make the `Consumable` class conform to the signature of function `f`.

It is worth noting that the problem of renaming causing programs to break is not something unique to structural typing, this can also occur in nominally typed programs. [Listing 22 on the facing page](#) showcases a program that breaks after renaming. In this listing we see that after renaming method `f` of class `A` the class no longer fulfill the requirements of the implementing interfaces `I`, as `I` expects a method `f` to be present, which it no longer is. We could resolve this by also performing an equal renaming to interface `I`. Although it is a problem in nominal PT as well, it is less so than with structural PT, since it can be resolved with just an additional renaming, and due to the relation being explicitly stated we can also give an error message during compilation notifying the programmer of this inconsistency. In structural PT we would have to disallow inline-types in order to make the problem more solvable for the programmer, but due to the relation between the class and interface not necessarily being explicitly stated it would be harder to give a sensible warning for the programmer.

With the discussed general advantages and disadvantages of structural and nominal type systems, and the points brought forward in this section we can see that both styles of typing have strong use cases with PT. A nominal type system in PT would seemingly lead to less problematic renaming scenarios, while a structural type system in PT would arguably fit better with the overall theme of PT, flexible re-use.

```

template T {
  class Consumable {
    i = 0;
  }

  class Consumer {
    function f(consumable : {i: number}) {
      ...
    }
  }
}

pack P {
  inst T { Consumable -> Consumable (i -> j) };
}

```

Listing 21: Example of how using renaming in PTS might break a program. After renaming the field `i` to `j` the class `Consumable` is no longer consumable by function `f` in class `Consumer`.

```

template T {
  interface I {
    void f();
  }

  class A implements I {
    void f() { ... }
  }
}

package P {
  inst T with A => A (f() -> g());
}

```

Listing 22: Example of how using renaming in PTj might break a program. After renaming the method `f` to `g` the class, `A`, no longer conform to the implementing interface `I`.

7.2 Attribute Renaming

Don't need full signature in PTS, because no overloading, etc. Might be easier to understand PTS version?

Chapter 8

Results

8.1 Future Works

8.1.1 Diamond Problem

essay

8.1.2 Improve the Compilers Error Messages

As I mentioned shortly in subsection [5.4.1 on page 33](#) tree-sitter does have support for giving position of a syntax node, and this could be utilized to produce better error messages.
